Question 1

What is the optimal value of alpha for ridge and lasso regression? What will be the changes in the model if you choose double the value of alpha for both ridge and lasso? What will be the most important predictor variables after the change is implemented?

Ans:-

Optimal value for ridge- 56 and lasso- 0.001, with increase in the value of lambda the models starts to underfit where the model complexity reduces to more than required. Which results in low variance and high bias, which means the training data has high error value. It causes model under learn from data.

But for lasso increase in alpha has penalises our model more and coefficient of variable will reduced to zero, along with that our r2 value drops by approx. 4%.

Once the change is implemented below mentioned variables are the most important predictor variables

- MSSubClass, MSSubClass, OverallCond, Fireplaces, GarageArea, YearBuilt

Question 2

You have determined the optimal value of lambda for ridge and lasso regression during the assignment. Now, which one will you choose to apply and why?

Ans-

I will choose Lasso regression, as it makes the coefficient values to zero for the features which has less importance with response variable, or we can say that it automatically does the feature selection for the model. The features with high importance remain for prediction.

Question 3

After building the model, you realised that the five most important predictor variables in the lasso model are not available in the incoming data. You will now have to create another model excluding the five most important predictor variables. Which are the five most important predictor variables now?

Ans:-

Most important variables-

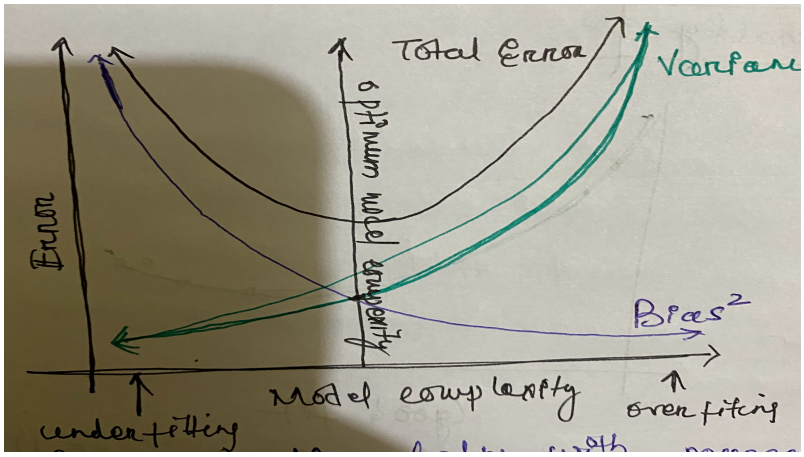
MSSubClass, BsmtFullBath, OverallCond, Fireplaces, GarageArea

Question 4

How can you make sure that a model is robust and generalisable? What are the implications of the same for the accuracy of the model and why?

Ans:-

The model should be as simple as required not more/less, though its accuracy will decrease but it will be more robust and generalisable. It can be also understood using the Bias-Variance trade-off. Graph. The simpler the model the more the bias but less variance and more generalizable. Its implication in terms of accuracy is that a robust and generalisable model will perform equally well on both training and test data i.e. the accuracy does not change much for training and test data.



Bias: Bias is error in model, when the model is weak to learn from the data. High bias means model is unable to learn details in the data. Model performs poor on training and testing data.

Variance: Variance is error in model, when model tries to over learn from the data. High variance means model performs exceptionally well on training data as it has very well trained on this of data but performs very poor on testing data as it was unseen data for the model. It is important to have balance in Bias and Variance to avoid overfitting and under-fitting of data.
